Functional Endoscopic Sinus Surgery for Chronic Rhinosinusitis

**POLICY**

The use of functional endoscopic sinus surgery in the treatment of chronic rhinosinusitis is considered medically necessary for patients with chronic rhinosinusitis when the following criteria are present:

1. Chronic rhinosinusitis symptoms, characterized by at least two of the following, at least one of which is (a) or (b), are present for at least 12 continuous weeks:
   a. Mucopurulent nasal drainage;
   b. Nasal congestion;
   c. Facial pain;
   d. Facial pressure;
   e. Anosmia or hyposmia.

   **AND**

2. Appropriate medical therapy has been attempted, including all of the following:
   a. Topical nasal steroids for at least 8 consecutive weeks;
   b. Nasal lavage for at least 8 consecutive weeks;
   c. Consideration for allergic and/or immune evaluation if the patient has symptoms consistent with allergic rhinitis and/or immunodeficiency.

   **AND**

3. There is objective evidence of mucosal inflammation as demonstrated by one of the following:
   a. Sinus computed tomography or magnetic resonance imaging showing significant mucosal thickening or opacification of the paranasal sinuses; **OR**
b. Nasal endoscopy with purulent mucus in the middle meatus or ethmoid region OR polyps in the nasal cavity or middle meatus.

AND

4. There are no serious urgent complications of acute sinusitis that would suggest orbital cellulitis or abscess, intracranial extension of infection, or other complication that would require urgent or emergent surgery such that “appropriate medical therapy” for 8 weeks would not be appropriate.

The use of functional endoscopic sinus surgery is considered investigational for the treatment of chronic rhinosinusitis when the above criteria are not met.

POLICY GUIDELINES

Criteria for “maximal medical therapy” used before endoscopic sinus surgery is attempted have been reported in a minority (21%) of published studies of endoscopic sinus surgery (Dautremont & Rudmik, 2015). The criteria used vary across studies, but studies that have reported specific criteria most often report using topical steroids (91.4%; mean duration, 8.4 weeks) and oral antibiotics (87.7%; mean duration, 23 days) (Dautremont & Rudmik, 2015). Systematic reviews of randomized controlled trials have consistently demonstrated improved symptoms of chronic rhinosinusitis with topical steroids. In contrast, weak evidence supports the use of systemic antibiotics in chronic rhinosinusitis.

BENEFIT APPLICATION

BlueCard/National Account Issues

State or federal mandates (eg, Federal Employee Program) may dictate that certain U.S. Food and Drug Administration–approved devices, drugs, or biologics may not be considered investigational, and thus these devices may be assessed only by their medical necessity.

BACKGROUND

Chronic Rhinosinusitis

CRS is a highly prevalent inflammatory disorder of the paranasal sinuses and the mucosa of the nasal passages that affects 3% to 7% of adults. In adults, CRS is characterized by symptoms related to nasal and sinus obstruction and inflammation, including mucopurulent nasal drainage, nasal congestion, facial pain or pressure, and anosmia or hyposmia, that persist for at least 12 weeks.

Three CRS subtypes exist and may have somewhat different treatment strategies: CRS without nasal polyposis; CRS with nasal polyposis; and allergic fungal sinusitis. The latter is a less common subtype thought to result from chronic allergic inflammation to colonizing nasal fungi. This evidence review focuses on the more common subtypes: CRS with and without nasal polyposis. Both subtypes present with similar symptoms. However, CRS with nasal polyposis is, by definition, associated with nasal polyps that are visible on rhinoscopy or nasal endoscopy. Further, CRS with nasal polyposis is more likely to be associated with asthma and aspirin intolerance; this triad is referred to as Samter syndrome or aspirin-exacerbated respiratory disease.

CRS is associated with impaired quality of life (QOL) for affected patients, and with high direct and indirect costs for medical treatments and lost productivity. Most often, the negative health effects of CRS are related to the unpleasant symptoms associated with CRS, including nasal congestion, nasal drainage, and facial pain or pressure. In rare cases, CRS can be associated with serious complications, including orbital cellulitis, osteomyelitis, or intracranial extension of infection.
While acute sinusitis is considered a more traditional infectious process, CRS is a chronic inflammatory disease of the upper airways, with multiple underlying causes. Risk factors for CRS with or without nasal polyps include anatomic variations and gastroesophageal reflux. There are conflicting reports about the association between allergy and CRS without nasal polyps, although weak evidence has suggested that allergy may be associated with CRS with nasal polyps. In addition, aspirin sensitivity may be associated with CRS with nasal polyps. The role of bacterial, viral, and fungal microorganisms in CRS has been actively investigated. There is some evidence that CRS is associated with a predominance of anaerobic bacteria.\(^2,3\) On the other hand, a study that used bacterial ribosomal RNA sequencing to evaluate the sinus microbiome in patients with and without CRS found a quantitative increase in bacterial and fungal RNA expression in patients with CRS, but no major differences in the types of microorganisms detected.\(^4\) Bacterial biofilms have been identified in cases of CRS.\(^5\)

**Diagnostic Criteria**

Several medical organizations have developed criteria for the diagnosis of CRS, which are summarized in Table 1. Most diagnostic schemas require the presence of the major symptoms of CRS for more than 12 weeks, combined with objective evidence of mucosal inflammation on sinus imaging, endoscopy or rhinoscopy, or both.

**Table 1. Chronic rhinosinusitis Diagnostic Criteria**

### Functional Endoscopic Sinus Surgery for Chronic Rhinosinusitis

#### Chronic Rhinosinusitis Definition

- Reduction or loss of smell
- And either
  - Endoscopic signs of:
    - Nasal polyps, and/or
    - Mucopurulent discharge primarily from middle meatus, and/or oedema/mucosal obstruction primarily in middle meatus
    - And/or
  - CT changes:
    - Mucosal changes within the ostiomeatal complex and/or sinuses

-Chronic rhinosinusitis with nasal polyps (CRSwNP): Chronic rhinosinusitis as defined above and bilateral, endoscopically visualised polyps in middle meatus.

-Chronic rhinosinusitis without nasal polyps (CRSsNP): Chronic rhinosinusitis as defined above and no visible polyps in middle meatus, if necessary following decongestant.

#### Diagnostic criteria for rhinosinusitis:

- Major symptoms – two of the following, one to be:
  - Nasal congestion or obstruction
  - Nasal discharge (anterior or posterior)
  - Facial pain or pressure
  - Olfactory disturbance
- And either
- Endoscopic signs (one or more of):
  - Polyps
  - Mucopurulent discharge from middle meatus
  - Oedema obstruction at middle meatus
- Or
- Computerised Tomography (CT) signs

- [12] weeks or longer of [2] or more of the following signs and symptoms:
  - Mucopurulent drainage (anterior, posterior, or both),
  - Nasal obstruction (congestion)
  - Facial pain-pressure-fullness, or
  - Decreased sense of smell.
- And

CRS: chronic rhinosinusitis; CRSsNP: chronic rhinosinusitis without nasal polyps; CRSwNP: chronic rhinosinusitis with nasal polyps; CT: computed tomography; MRI: magnetic resonance imaging.

Evaluation of patients for allergic disorders, immunodeficiencies, or both, may be indicated depending on the presence of associated symptoms.

### Medical Treatment

Medical therapy for CRS, with or without polyps, is often multimodal, including nasal irrigation, topical and/or systemic corticosteroids, and/or antibiotic therapy. Guidelines from the American Academy of Otolaryngology-Head and Neck Surgery (2015) have recommended the use of saline nasal irrigation, topical intranasal corticosteroids, or both, for symptom relief of CRS, on the basis of systematic reviews of randomized controlled trials (RCTs). There is a specific recommendation against the use of topical and systemic antifungal therapies. The guidelines do not include a statement specifically addressing the use of systemic antibiotics for CRS; however, in the list of future research needs, the authors included: “Perform additional RCTs to clarify the impact of antibiotic therapy on CRS outcomes.”

A systematic review by Rudmik and Soler (2015) evaluated the evidence for various medical therapies for chronic sinusitis, excluding allergic fungal sinusitis. Reviewers included 29 studies, with 12 meta-analyses (with a total of >60 RCTs), 13 systematic reviews, and 4 individual RCTs not included in any meta-analyses. Topical corticosteroids were associated, in multiple studies, with improved symptom scores, reduced polyp size, and decreased polyp recurrence after surgery. Saline nasal irrigation was associated, in multiple studies, with significant improvements in symptoms scores. There was some evidence that two systemic therapies (oral corticosteroids, doxycycline), both for three weeks, improved polyp scores in patients with CRS with nasal polyps. Long-term (>3 months) macrolide therapy was associated in an RCT with improved symptoms and QOL in individuals with CRS without nasal polyps, although other studies did not find a benefit with chronic macrolide use.

In 2014, an evidence-based review summarized a series of earlier evidence-based reviews with recommendations related to CRS. This review concluded that both saline irrigation and topical corticosteroids are well-supported by the available published literature for treatment of CRS, with and without nasal polyps. For CRS with polyps, the evidence demonstrated short-term improvement in symptoms after short-term oral corticosteroid treatment. For CRS with or without nasal polyps, a small number of RCTs have shown improvement in nasal endoscopy scores and some symptoms with oral macrolide therapy. However, for CRS with or without nasal polyps, there was very limited evidence on the use of nonmacrolide oral antibiotics.

A 2011 Cochrane review of studies comparing systemic antibiotics with placebo for CRS in adults identified a study (n=64 patients) judged to be at high-risk of bias. Reviewers concluded: “Further good quality trials, with large sample sizes, are needed to evaluate the use of antibiotics in chronic rhinosinusitis.”

### Surgical Treatment
The goals of surgery for CRS include removing polyps and debris that may be sources of inflammatory mediators and prevent the effective delivery of local medical therapies. In addition, to varying degrees, surgical techniques involve the creation of open sinus cavities, usually via dilation of the sinus ostia, to permit better drainage from the sinus cavities and more effective delivery of local therapies.

Techniques for functional endoscopic sinus surgery (FESS), in which an endoscope is used to access the sinus cavities and varying degrees of tissue are removed and the sinus ostia are opened, have evolved since the development of the nasal endoscope in the 1960s. FESS has largely replaced various open techniques for CRS (eg, Caldwell-Luc procedure), although open procedures may have a role in complicated sinus pathologies (eg, endonasal tumors).

FESS encompasses a variety of degrees of sinus access and tissue removal and is described based on the sinuses accessed. The Draf classification is used to describe degrees of endoscopic frontal sinusotomy (see Table 2).

**Table 2. Draf Classification for Endoscopic Frontal Sinusotomy**

*a Modified Lothrop procedure.

FESS can also be used to access the ethmoid sinuses, which may involve creation drainage into the maxillary sinuses (maxillary antrostomy).

**Outcomes**

To quantify the severity of CRS and to assess treatment response, various outcomes measures can be used, including patient-reported QOL measures, radiologic scores, and endoscopic grading.

The Lund-McKay scoring system uses radiologist-rated information derived from computed tomography scans regarding opacification of the sinus cavities, generating a score ranging from 0 to 12.\(^{15,16}\)

Several disease-specific patient-reported QOL scores have been used. Commonly used is the Sino-Nasal Outcome Test-20 (SNOT-20), a validated questionnaire, in which patients complete 20 symptom questions on a categorical scale (0 [no bother] to 5 [worst symptoms can be]). Average rankings can be reported over all 20 symptoms, as well as by 4 subclassified symptom domains. The SNOT-22 is a variation of the SNOT-20 that includes 2 additional questions (“nasal obstruction” and “loss of smell and taste”). The minimal clinically important difference for the SNOT-22 has been estimated to be 8.9 points.\(^{17}\)

Additionally, QOL may be reported based on overall health-related QOL scores, such as the 36-Item Short-Form Health Survey. The Survey consists of 8 scales on various health domains, which are transformed into a scale ranging from 0 to 100 (100 corresponding to best health).

**Regulatory Status**
FESS is a surgical procedure and, as such, is not subject to regulation by the U.S. Food and Drug Administration.

**RATIONALE**

This evidence review was created in October 2016 with a search of the MEDLINE database. The most recent literature update was performed through January 11, 2019.

Evidence reviews assess the clinical evidence to determine whether the use of technology improves the net health outcome. Broadly defined, health outcomes are the length of life, quality of life (QOL), and ability to function—including benefits and harms. Every clinical condition has specific outcomes that are important to patients and managing the course of that condition. Validated outcome measures are necessary to ascertain whether a condition improves or worsens; and whether the magnitude of that change is clinically significant. The net health outcome is a balance of benefits and harms.

To assess whether the evidence is sufficient to draw conclusions about the net health outcome of technology, two domains are examined: the relevance, and quality and credibility. To be relevant, studies must represent one or more intended clinical use of the technology in the intended population and compare an effective and appropriate alternative at a comparable intensity. For some conditions, the alternative will be supportive care or surveillance. The quality and credibility of the evidence depend on study design and conduct, minimizing bias and confounding that can generate incorrect findings. The randomized controlled trial (RCT) is preferred to assess efficacy; however, in some circumstances, nonrandomized studies may be adequate. RCTs are rarely large enough or long enough to capture less common adverse events and long-term effects. Other types of studies can be used for these purposes and to assess generalizability to broader clinical populations and settings of clinical practice. The following is a summary of the key literature to date.

This review focuses on the use of surgical therapies for chronic rhinosinusitis (CRS) with or without nasal polyposis. It focuses on functional endoscopic sinus surgery (FESS).

The primary outcome measures relevant to the treatment of CRS are patient-reported symptoms and QOL. Studies should predefine responder criteria for outcome measures used and assess between-group differences in the proportion of patients considered responders. Examiner evaluation of the nasal and sinus appearance and polyp size may provide some information about treatment outcomes, but these evaluations are limited by the lack of universally accepted standards.

Functional Endoscopic Sinus Surgery for Chronic Rhinosinusitis

**Clinical Context and Test Purpose**

The purpose of FESS is to provide a treatment option that is an alternative to or an improvement on existing therapies, such as medical management, in patients with CRS with or without nasal polyposis.

The question addressed in this evidence review is: does FESS improve the net health outcome for patients with CRS?

The following PICOTS were used to select literature to inform this review.

**Patients**

The relevant population of interest are individuals with CRS with or without nasal polyposis.

**Interventions**

The therapy being considered is FESS.
Comparators
Comparators of interest include medical management. Medical management for CRS includes saline nasal irrigation, corticosteroids, antibiotics, and immunotherapy.

Outcomes
The general outcomes of interest are symptoms, change in disease status, QOL, treatment-related morbidity.

Timing
The existing literature evaluating FESS as a treatment for CRS with or without nasal polyposis has varying lengths of follow-up, ranging from 3- to 12-months. While studies described below all reported at least one outcome of interest, longer follow-up was necessary to fully observe outcomes. Therefore, 12-months of follow-up is considered necessary to demonstrate efficacy.

Setting
Patients with CRS with or without nasal polyposis are actively managed by otolaryngologists and primary care providers in an inpatient clinical setting.

Study Selection Criteria
Methodologically credible studies were selected using the following principles:

a. To assess efficacy outcomes, comparative controlled prospective trials were sought, with a preference for RCTs;

b. In the absence of such trials, comparative observational studies were sought, with a preference for prospective studies.

c. To assess long-term outcomes and adverse events, single-arm studies that capture longer periods of follow-up and/or larger populations were sought.

Studies with duplicative or overlapping populations were excluded.

Despite the widespread use of FESS, only a small number of RCTs have directly compared FESS with medical management. To the extent possible, CRS with and without nasal polyposis have been evaluated separately. If studies did not specify that the patient populations included only those with CRS with nasal polyposis, or if studies included both groups, the study was grouped with those addressing CRS with and without nasal polyps.

FESS for CRS
Despite the widespread use of FESS, only a small number of RCTs have directly compared FESS with medical management. To the extent possible, CRS with and without nasal polyposis have been evaluated separately. If studies did not specify that the patient populations included only those with CRS with nasal polyposis, or if studies included both groups, the study was grouped with those addressing CRS with and without nasal polyps.

CRS With or Without Polyposis
Two RCTs were identified that compared FESS with medical therapy in patients with CRS, not limited to patients with polyposis, which have been summarized in systematic reviews. Given the small body of RCTs, they are discussed individually first, followed by systematic reviews.

Randomized Controlled Trials
Ragab et al (2004) reported on the results of an RCT comparing medical management with FESS in patients who had CRS with or without nasal polyposis. Eligible patients had 1 of the following: 8 or more weeks of persistent signs and symptoms and signs at least 2 major or 1 major and 2 minor symptoms (major: nasal congestion obstruction, nasal discharge, facial pain or pressure, headache, olfactory disturbance; minor: fever, halitosis [97% of patients]) or 4 episodes per year of recurrent acute rhinosinusitis each lasting at least 10 days in association with persistent changes on computed tomography for weeks after medical therapy without intervening acute infection (3% of patients). Patients were randomized after demonstrating persistent symptoms following initial medical therapy and subsequently demonstrating persistent changes in computed tomography scan. Patients were randomized to an FESS group, which received FESS performed by 1 of 2 surgeons, followed by a 2-week course of oral erythromycin, topical nasal dexamethasone plus tramazoline, and alkaline nasal douche, followed by a 3-month course of topical nasal fluticasone, or to a medical therapy group, which received a 12-week course of oral erythromycin, alkaline nasal douche, and topical nasal corticosteroids (dexamethasone plus tramazoline for 2 weeks followed by 10 weeks of fluticasone for patients without polyposis and 12 weeks of fluticasone for patients with polyposis).

Of 90 patients randomized, 35 had CRS with polyposis. Both patient-reported (Sino-Nasal Outcome Test-20 [SNOT-20], 36-Item Short-Form Health Survey, subjective symptom assessment on visual analog scale) and objective (nasal examination with scoring, acoustic rhinometry, saccharine clearance time, total nasal nitric oxide levels) outcomes were used, without blinding of outcome assessment. At 6- and 12-month follow-up visits, both groups demonstrated significant improvements in subjective outcomes, but there were no significant between-group differences. For example, the percent change in visual analog scale score at 6 months was 49.7% in the FESS group compared with 45.3% in the medical therapy group (p>0.05). There were no significant differences in the change in SNOT-20 or 36-Item Short-Form Survey scores between groups (p<0.05). There were no significant between-group differences in change in any objective measurements at 6- or 12-month follow-up visits, with the exception of total nasal volume at 6 months in patients without polyposis (mean percent change from baseline, 21.8% in the FESS group vs 3.2% in the medical therapy group; p<0.01).

A second report (Ragab et al [2006]) assessed asthma-related outcomes in the subgroup of 45 patients with asthma, and a third (Ragab et al [2010]) detailed the QOL measurement outcomes in this study. Hartog et al (1997) reported on results of an RCT comparing FESS plus sinus irrigation with sinus irrigation alone in patients with chronic maxillary sinusitis. Eligible patients had at least two of the following three CRS symptoms: purulent rhinitis, nasal obstruction, and headache, with confirmation of maxillary sinusitis on sinus radiographs. Patients were randomized to sinus irrigation, with a second irrigation a week after the first if needed, or to FESS within three days of enrollment. Randomization techniques were not described. The trial enrolled 89 patients (45 in each group), with 77 patients included in data analysis; 11 patients were nonevaluable (7 with early dropout due to treatment failure; 5 for other reasons). An additional 14 patients were lost to follow-up. Symptom scores and mucosal appearance on nasal endoscopy (scored on a 1-4 scale) were evaluated at baseline and 2, 6, 12, and 52 weeks after enrollment. Sinus radiographs were reevaluated at 12 weeks. For patient-reported symptoms, the prevalence of purulent rhinitis decreased from 91% to 40% after sinus irrigation alone and from 86% to 16% after sinus irrigation plus FESS (p=0.027), while the prevalence of loss of smell decreased from 49% to 18% after sinus irrigation and from 51% to 11% after sinus irrigation plus FESS (p=0.026). Changes in other patient-reported outcomes, including snoring, nasal obstruction, headache, and dry mouth on waking, did not differ significantly between groups. Nasoendoscopy-based scores of mucosal swelling and the prevalence of middle turbinate purulence did not differ significantly between groups at any follow-up time point. The proportion of patients in each group with specific findings on
sinus radiographs (complete opacity, fluid level, mucosal swelling of at least 50% of the mediolateral diameter of the maxillary sinus) or with normal sinus radiographs at 12-week follow-up did not differ significantly between groups.

A 2006 Cochrane review summarized the evidence on FESS for CRS. This review was updated in 2010, with a literature search through November 2008, with no change to reviewers’ conclusions. Reviewers included RCTs comparing FESS alone or FESS plus other therapies with medical treatment and/or other types of sinus surgery. Three RCTs (total n=212 patients) met reviewers’ inclusion criteria, one of which was unpublished: one compared FESS plus sinus irrigation and medical treatment (antibiotics) with medical treatment alone; another compared endoscopic middle meatal antrostomy with conventional inferior meatal antrostomy; and a third compared FESS plus medical treatment (antibiotics, combination steroid and decongestant nasal spray, and nasal irrigation, followed by steroid nasal spray and saline nasal irrigation) with medical treatment alone. For the risk of bias assessment, reviewers reported: “It was unclear whether allocation concealment was carried out in any of the trials. There was no blinding applied in any of the included studies. Intention-to-treat analysis was applied in two of the studies.” Two trials reported no between-group differences in symptom scores at follow-up, and the third reported no between-group differences in overall cure rates. No major complications were reported across the three studies.

Vlastarakos et al (2013) reported on results of a systematic review and meta-analysis of FESS for CRS with or without nasal polyps in children, which included any interventional studies. Reviewers selected 4 prospective, 5 retrospective comparative, and 6 retrospective studies (total n=1301 treated patients); no RCTs were identified. Although reviewers concluded that FESS was associated with improvements in patients’ QOL, the conclusions that can be drawn from retrospective studies are limited.

Patel et al (2017) conducted a systematic review with meta-analysis comparing appropriate medical therapy with endoscopic sinus surgery in adults who had CRS, including only moderate- to high-quality prospective studies. Six observational or before/after studies were selected; no RCTs were included. For the pooled analysis of disease-specific QOL measures, 2 studies (n=106 patients) were included. The studies used different outcome measures, the Rhinosinusitis Disability Index and SNOT-22, and were therefore pooled using the standardized mean difference. There was significant heterogeneity (p<0.001, I²=97%) but both studies favored surgery. For the pooled analysis of endoscopic grading scores, 2 studies (n=182 patients) were combined, again with significant heterogeneity (p=0.004, I²=88%). Mean scores in both studies favored surgery.

Systematic Reviews

Goldstein and Kennedy (2013) reported on results of a systematic review of the long-term (>1 year) outcomes after surgical therapy for sinusitis, including endoscopic sinus surgery, balloon ostial dilation, and hybrid procedures. Reviewers included 56 studies, 30 of which reported on follow-up beyond 1 year. They did not report specifically on study quality or design; however, they described noncomparative studies that reported high rates of improvement in symptoms (>75%) after 1 year.

CRS with Polyposis

Surgical approaches may include a simple polypectomy (defined as the removal of polyps without intentionally entering the sinuses or enlarging the natural ostia), polypectomy with FESS (removing polyps and other causes of obstruction from the ethmoid sinuses and lateral or nasal wall), or more radical nasalization of the ethmoid sinuses. We focus on studies comparing FESS with medical therapy for the management of CRS with nasal polyps.

Randomized Controlled Trials
Functional Endoscopic Sinus Surgery for Chronic Rhinosinusitis

Two RCTs identified are relevant to the use of FESS in patients with CRS with polyposis. In the Ragab et al (2004) trial (described above), 39% of patients had nasal polyposis.16 No significant differences were reported between FESS and medical treatment for change in subjective or objective outcome measures.

Alobid et al (2005) reported on an RCT comparing FESS with oral steroids for individuals who had nasal polyposis, with a focus on nasal symptoms, polyp size, and QOL.26 Eligible patients had nasal polyposis, defined by the presence of both of the following: visualization of polyps under endoscopic examination and bilateral opacification of paranasal sinuses on computed tomography scan. Patients were randomized to 14 days of oral prednisone (n=52) or to FESS (n=56). All patients received 1 year of intranasal budesonide for 12 months. Symptoms were patient-reported on a 0-to-3 scale, while nasal polyp score was endoscopically assessed on a scale ranging from 0 to 3. At the 6- and 12-month follow-ups, patients in both groups reported improvements in nasal symptoms. At six months, the FESS group had greater improvements than the medical therapy group in nasal symptom scores (1.6 for FESS vs 1.2 for medical therapy, p<0.05), loss of smell scores (0.9 for FESS vs 0.5 for medical therapy, p<0.05), and polyp size score (2.3 for FESS vs 0.8 for medical therapy, p<0.05).

Systematic Reviews

Two Cochrane reviews published in 2014 addressed the use of surgical therapies for CRS with nasal polyps. Rimmer et al (2014), compared surgical interventions with medical interventions for CRS with nasal polyps.27 Sharma et al (2014), compared the value of nasal polypectomy plus additional sinus dissection with polypectomy alone for CRS with nasal polyps.28

The Rimmer et al (2014) review selected RCTs comparing any surgical intervention with any medical treatments, including placebo, in adults with CRS with nasal polyps.27 Reviewers identified 4 studies (total n=231 randomized participants), none of which was considered at low-risk of bias. In all trials, topical steroids were used in both arms, but the trials otherwise varied by comparison groups; 1 study (n=109 enrolled, 95 analyzed) compared FESS with systemic steroids, 2 studies (combined n=87) compared polypectomy with systemic steroids, and 1 study (n=35) compared FESS plus a topical steroid (usual dose) with antibiotics plus high-dose topical steroid. Across trials, there were no important differences between treatment groups in terms of patient-reported disease severity scores, disease-specific QOL scores (eg, SNOT-22), or overall health-related QOL scores. Two trials reported on endoscopic sinus mucosal appearance, although there is no single accepted endoscopic grading system. In the RCT (n=95 analyzed) comparing FESS with systemic steroids, polyp size scores (graded on a 0-3, point scale) were significantly better in the FESS group (mean difference, -1.5; 95% confidence interval, -1.8 to 0 -1.2; corresponds to large effect size). In the RCT (n=34) comparing FESS plus topical steroid with antibiotics plus topical steroids, polyp size was also graded on a scale from 0 to 3 but reported as a percentage improvement from baseline in each group. The percentage improvement did not differ significantly between groups (mean difference=2.3%; 95% confidence interval, -17.4% to 12.8%), but the estimate for this improvement was limited due to the small sample size. Overall, reviewers concluded: “Evidence relating to the effectiveness of different types of surgery vs medical treatment for adults with CRS with nasal polyps is of very low quality. The evidence does not show that one treatment is better than another in terms of patient-reported symptom scores and quality of life measurements.”

The Sharma et al (2014) review included RCTs and quasi-RCTs comparing nasal polypectomy with surgeries that involved more extensive sinus clearance in adults with CRS with nasal polyps.28 Reviewers identified no studies that met their inclusion criteria. Six studies were excluded after full-text review, for a variety of reasons, including the use of a “split-nose” design, lack of randomization, the use of patient populations that did not necessarily have nasal polyps or the use of surgical techniques not included in reviewers’ criteria. Reviewers concluded: “We are unable to reach any conclusions as to whether
isolated nasal polypectomy or more extensive sinus surgery is a superior surgical treatment modality for chronic rhinosinusitis with nasal polyps.8"

Other evidence-based reviews, such as those on adult CRS reported by Orlandi et al (2014),13 on surgery for CRS with or without nasal polyps reported by Georgalas et al (2014),25 and on CRS with nasal polyps by Schlosser and Soler (2013),30 did not describe their search and selection criteria.

**Section Summary: FESS for CRS**

The evidence from RCTs comparing FESS with medical management in individuals who had CRS with or without nasal polyposis is limited. Multiple observational studies and single-arm trials, with methodologic limitations, generally have not reported clinically significant differences in symptom improvements with FESS compared with medical therapy. Controlled trials with low-risk of bias are important to determine the efficacy of FESS compared with the alternatives.

**Summary of Evidence**

For individuals with CRS with or without nasal polyposis who receive FESS, the evidence includes RCTs and systematic reviews. The relevant outcomes are symptoms, change in disease status, QOL, and treatment-related morbidity. A small number of trials, with methodologic limitations, generally have not reported clinically significant differences in symptom improvement with FESS compared with medical therapy. Two Cochrane reviews evaluating FESS for CRS with and without nasal polyposis have reported that FESS can be accomplished safely, but clinical trials have not demonstrated significant improvements with FESS compared with standard medical therapy. The evidence is insufficient to determine the effects of the technology on health outcomes.

**SUPPLEMENTAL INFORMATION**

**Clinical Input from Physician Specialty Societies and Academic Medical Centers**

While the various physician specialty societies and academic medical centers may collaborate with and make recommendations during this process, through the provision of appropriate reviewers, input received does not represent an endorsement or position statement by the physician specialty societies or academic medical centers, unless otherwise noted.

In response to requests, input was received from 2 specialty societies and 3 academic medical centers (4 responses), for a total of 6 responses, while this policy was under review in 2016. Input was consistent that the use of functional endoscopic sinus surgery is medically necessary for the treatment of chronic rhinosinusitis (CRS). Opinions about specific criteria for the diagnosis of CRS differed, although most reviewers provided some for diagnosis of CRS and failure of medical management.

**Practice Guidelines and Position Statements**

The American Academy of Otolaryngology-Head and Neck Surgery (2015) updated its clinical practice guidelines on the management of sinusitis in adults, which recommended the following on the diagnosis and treatment of CRS (see Table 3).11

**Table 3. Guidelines on Management of CRS in Adults**

<table>
<thead>
<tr>
<th>Guideline</th>

<td>Recommendation (against therapy)</td>
<td>A (systematic reviews of RCTs)</td>
<td>High</td>
</tr>
</tbody>
</table>

CRS: chronic rhinosinusitis; RCT: randomized controlled trial.

**U.S. Preventive Services Task Force Recommendations**

Not applicable.

**Medicare National Coverage**

There is no national coverage determination. In the absence of a national coverage determination, coverage decisions are left to the discretion of local Medicare carriers.

**Ongoing and Unpublished Clinical Trials**

A search of ClinicalTrials.gov in January 2019 did not identify any ongoing or unpublished trials that would likely influence this review.

**ESSENTIAL HEALTH BENEFITS**

The Affordable Care Act (ACA) requires fully insured non-grandfathered individual and small group benefit plans to provide coverage for ten categories of Essential Health Benefits (“EHBs”), whether the benefit plans are offered through an Exchange or not. States can define EHBs for their respective state.

States vary on how they define the term small group. In Idaho, a small group employer is defined as an employer with at least two but no more than fifty eligible employees on the first day of the plan or contract year, the majority of whom are employed in Idaho. Large group employers, whether they are self-funded or fully insured, are not required to offer EHBs, but may voluntary offer them.

The Affordable Care Act requires any benefit plan offering EHBs to remove all dollar limits for EHBs.
